What's next

The shape of an ideal
tetrahedron embedded in \mathbb{H}^3
is determined by a single
complex dihedral angle (aka
cross ratio) $z \in \mathbb{C} \setminus \{0, 1\}$.

Around an edge of the
triangulation \mathcal{T} of M the
product of the complex
dihedral angles must be 1
(gluing equation for this edge).

These conditions give us
polynomials in the complex
angles. The set of such
solutions is the deformation
variety, $\mathcal{D}(M; \mathcal{T})$.

What's next

The shape of an ideal tetrahedron embedded in \mathbb{H}^3 is determined by a single complex dihedral angle (aka cross ratio) $z \in \mathbb{C} \setminus \{0, 1\}$.

Around an edge of the triangulation \mathcal{T} of M the product of the complex dihedral angles must be 1 ([gluing equation](#) for this edge).

These conditions give us polynomials in the complex angles. The set of such solutions is the deformation variety, $\mathcal{D}(M; \mathcal{T})$.

The Developing Map

Given a point $p \in \mathcal{D}(M; \mathcal{T})$ the developing map is

$$\Phi_p : \tilde{M} \rightarrow \mathbb{H}^3$$

Defined by developing paths of tetrahedra into \mathbb{H}^3 by tracking their vertices on $\partial\mathbb{H}^3$, starting from some initial triangle T_0 of $\tilde{\mathcal{T}}$ ($\tilde{\mathcal{T}}$ is the lift of \mathcal{T} to \tilde{M}).

- ▶ Defined up to conjugation, both in the choice of images of vertices of T_0 , and choice of T_0 among the triangles of $\tilde{\mathcal{T}}$.
- ▶ Doesn't depend on the choice of path of tetrahedra because of the gluing equations.
- ▶ Some tetrahedra in \mathbb{H}^3 can end up flat or negatively oriented, but never such that two vertices are in the same place on $\partial\mathbb{H}^3$ (degenerate).
- ▶ Φ_p gives us a representation into $\text{Isom}(\mathbb{H}^3)$ and so a (generally incomplete) hyperbolic structure.

What's next

How are $\mathcal{D}(M; T_2)$ and $\mathcal{D}(M; T_3)$ related?

Outside of the six sided polyhedron, nothing changes...

$$a = \frac{y-1}{y(1-x)}$$

$$b = \frac{x-1}{x(1-y)}$$

$$c = \frac{1}{ab}$$

$$x = \frac{a-1}{a(1-b)}$$

$$y = \frac{b-1}{b(1-a)}$$

Everything translates unless $x = 1/y$, which corresponds to the top and bottom vertices of the two tetrahedra developing to the same place on $\partial \mathbb{H}^3$. The corresponding three tetrahedra are all degenerate.

What do these moves do to the deformation variety?

The degenerate case

What's next

This behaviour happens with very simple manifolds and triangulations: e.g. the punctured torus bundle with monodromy LLR has triangulations \mathcal{T} and \mathcal{T}' with 4 and 5 tetrahedra respectively such that \mathcal{T} has an entire component with " $x = 1/y$ ", and to which there is no corresponding component for \mathcal{T}' .

We would like to be able to define some extension of the deformation variety which deals with degenerate tetrahedra:

- ▶ How do we define a developing map when some tetrahedra are degenerate?
- ▶ How do we compactify $\mathcal{D}(M; \mathcal{T})$? (in order to add ideal points)
- ▶ How do we include "ideal components"?

should become

$$\Phi_{\tilde{p}} : \tilde{M} \rightarrow (\text{tree of } \mathbb{H}^3\text{'s})$$

Developing into $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Previously, we developed ideal tetrahedra into \mathbb{H}^3 by tracking positions of vertices on $\partial\mathbb{H}^3 = \mathbb{CP}^1$, now we need to track positions of vertices on $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Instead of \mathbb{CP}^1 we use *Serre's tree* (so called by Ohtsuki), T_ζ , tree with ends $\mathbb{C}((\zeta)) \cup \{\infty\}$. (Laurent series, plus ∞)

What's next

Developing into $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Previously, we developed ideal tetrahedra into \mathbb{H}^3 by tracking positions of vertices on $\partial\mathbb{H}^3 = \mathbb{CP}^1$, now we need to track positions of vertices on $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Instead of \mathbb{CP}^1 we use **Serre's tree** (so called by Ohtsuki), T_ζ , tree with ends $\mathbb{C}((\zeta)) \cup \{\infty\}$. (Laurent series, plus ∞)

Developing into $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Previously, we developed ideal tetrahedra into \mathbb{H}^3 by tracking positions of vertices on $\partial\mathbb{H}^3 = \mathbb{CP}^1$, now we need to track positions of vertices on $\partial(\text{tree of } \mathbb{H}^3\text{'s})$

Instead of \mathbb{CP}^1 we use **Serre's tree** (so called by Ohtsuki), T_ζ , tree with ends $\mathbb{C}((\zeta)) \cup \{\infty\}$. (Laurent series, plus ∞)

We develop in the same way: given $a, b, c \in \mathbb{C}((\zeta)) \cup \{\infty\}$ and knowing that the cross ratio (aka dihedral angle) z of (a, b, c, d) is given for this tetrahedron and

$$z = \frac{(a - c)(b - d)}{(a - d)(b - c)} \in \mathbb{C}((\zeta)) \setminus \{0, 1\}$$

We can solve for d :

$$d = \frac{(b - c)za - (a - c)b}{(b - c)z - (a - c)}$$

We also need consistency of the developing map through different paths of tetrahedra.

We develop in the same way: given $a, b, c \in \mathbb{C}((\zeta)) \cup \{\infty\}$ and knowing that the cross ratio (aka dihedral angle) z of (a, b, c, d) is given for this tetrahedron and

What's next

Cross ratios in $\mathbb{C}((\zeta))$: By some algebraic geometry magic, we can parametrise a neighbourhood of \tilde{p} by a complex variable ζ (with $\zeta = 0$ corresponding to \tilde{p}). For each tetrahedron, the cross ratio $z_i = z_i(\zeta) \in \mathbb{C}((\zeta))$.

Develop consistently: For all $\zeta \neq 0$ the $z_i(\zeta)$ develop cusp positions consistently, because they correspond to shapes of tetrahedra that satisfy the gluing equations, so the $z_i(\zeta)$ develop consistently as elements of $\mathbb{C}((\zeta))$.

For an isolated ideal point of $\mathcal{D}(M; T_3)$ corresponding to " $x = 1/y$ " in $\mathcal{D}(M; T_2)$ this gives us the right developing map into one "central" \mathbb{H}^3 of the tree.

Example: developing an ideal point into T_ζ

What's next

The combinatorial data of spines and how they glue together allows us to develop a purely combinatorial tree from the degeneration data. We require that this construction be independent of the path of tetrahedra we develop along.

This consistency implies that the normal triangles and quadrilaterals link up to form a spun-normal surface $S \subset \tilde{M}$ (related to work of Tillmann).

We can then define a tree T_S with vertices the components of $\tilde{M} \setminus S$ and edges corresponding to the components of S , and T_S is the same as the tree we get by gluing spines.

In the ideal point case the developing map gives T_S mapping into T_ζ , and components of $\tilde{M} \setminus S$ mapping to vertices of T_ζ .

We can then define a tree T_S with vertices the components of $\tilde{M} \setminus S$ and edges corresponding to the components of S , and T_S is the same as the tree we get by gluing spines.

In the ideal point case the developing map gives T_S mapping into T_ζ , and components of $\tilde{M} \setminus S$ mapping to vertices of T_ζ .

Theorem Suppose we have a set of $z^{(i)}(\zeta)$, one for each tetrahedron of \mathcal{T} such that the tree generated by the spines of lengths given by the orders of the $z^{(i)}$ is consistent. Let \tilde{M}_0 be a component of $\tilde{M} \setminus S$ and suppose a is the developed position of a vertex obtained from a path of tetrahedra that has a contiguous non-empty intersection with \tilde{M}_0 . Then a_H depends only on the lowest order terms of the $z^{(i)}(\zeta)$.

What this means is that we can work out the developing map for one vertex (one \mathbb{H}^3) of the T_ζ knowing only the orders and the lowest order coefficients of the cross ratios.

We still need some conditions on these coefficients to get that the developing map is independent of the path of tetrahedra we take to get to a vertex.

We still need some conditions on these coefficients to get that the developing map is independent of the path of tetrahedra we take to get to a vertex.

The extension to the deformation variety, $\tilde{\mathfrak{D}}(M, \mathcal{T})$ then should consist of points containing the following data:

- ▶ Order and choice of degeneration of cross ratio $z^{(i)}$ for each tetrahedron.
- ▶ Lowest order coefficient for each $z^{(i)}$.

subject to the conditions that:

- ▶ The spines corresponding to the combinatorial degeneration information fit together into a consistent tree.
- ▶ The positions of vertices a_H developed from paths following each component \tilde{M}_0 are independent of the path.

What's next

- ▶ Is this structure actually a variety?
- ▶ Does this work nicely with the 2-3 and 3-2 moves?
- ▶ Given triangulations $\mathcal{T}, \mathcal{T}'$ and a point $x \in \tilde{\mathcal{D}}(M, \mathcal{T})$, is there a corresponding $x' \in \tilde{\mathcal{D}}(M, \mathcal{T}')$? If so, we effectively have a triangulation independent structure.
- ▶ We should then, for instance, be able to take limits of points of the extended deformation variety(?) to (even more ideal) ideal points.
- ▶ This could then give us a way to look for essential surfaces from ideal points, and know that we would get all possible such surfaces, no matter which triangulation we used.
